

What is the SD signal of an optical module

Overview

There have been multiple variants of the electrical interface of optical modules that have been used over the years. The earliest forms of optical modules had an analog NRZ electrical interface. In the transmit direction, the optical module would directly drive the laser or LED with the analog signal coming from the front system card.

Key Takeaways

An SD signal in an optical module refers to a Synchronous Digital signal, typically part of an SDH/SONET network, transmitted as a framed, time-division multiplexed data stream over fiber through the module.

An optical module is a hot-pluggable transceiver that converts electrical signals into optical signals and vice versa, operating at the physical layer of the OSI model . It contains a Transmitter Optical Sub-Assembly (TOSA), which converts electrical input into modulated light using a laser diode or LED, and a Receiver Optical Sub-Assembly (ROSA), which converts incoming optical signals back into electrical signals . The module interfaces electrically with the host system and optically with the fiber network.

Understanding SD Signals

SD signals are the fundamental data streams in Synchronous Digital Hierarchy (SDH) or Synchronous Optical Network (SONET) systems . They are time-division multiplexed (TDM), meaning multiple lower-rate signals are combined into a higher-rate stream in a synchronized manner. For example, an STM-1 frame (the basic SDH unit) carries 155 Mbit/s and is structured in a two-dimensional frame of 9 rows by 270 columns of bytes. The frame includes:

- Section Overhead (SOH): Provides error monitoring, network management, and protection switching.
- Virtual Container (VC): Contains the actual payload data, subdivided into smaller containers (VC12, VC3) for granular access .

SD Signal Transmission via Optical Modules

When an SD signal is transmitted through an optical module:

- The electrical SD signal from the host system enters the module.
- The driver circuitry modulates the laser diode in the TOSA to emit an optical signal corresponding to the SD bit stream .
- The optical signal travels through the fiber to the receiving module.
- The ROSA converts the optical signal back into an electrical SD signal, preserving the frame structure and timing for further processing . This process ensures that synchronous, high-bandwidth data streams are reliably transmitted over long distances with minimal signal degradation.

Key Points

- SD signals are synchronous, framed, and multiplexed, allowing precise timing and efficient bandwidth utilization.
- Optical modules act as the physical layer interface, enabling SD signals to traverse fiber networks.
- The combination of SDH framing and optical transmission ensures robust, high-speed communication suitable for telecom and enterprise networks. In summary, the SD signal of an optical module is the electrical representation of a synchronous digital stream (SDH/SONET) that the module converts to optical form for transmission over fiber, maintaining the structured frame and timing essential for network synchronization .
